

Analysis of the risk factors related to the immune humoral anti-*Anaplasma marginale* in dairy cattle

Análise dos fatores de risco relacionados à resposta imune humoral anti-*Anaplasma marginale* em vacas de leite

Jenevaldo Barbosa da Silva^{1*}; Adivaldo Henrique da Fonseca²

Abstract

Anaplasma marginale is the most prevalent pathogen of cattle transmitted by ticks in the world. This study aimed to evaluate the risk factors for anaplasmosis in dairy cattle. Fifty dairy cattle from the herd of Empresa de Pesquisa Agropecuária do Estado do Rio de Janeiro were selected by proportional stratified sampling. The risk factors evaluated were: physiological state, race pattern, number of lactations, milk production, infestation by *Rhipicephalus microplus* and animal density. Antibody activity against *A. marginale* was determined using the indirect enzyme-linked immunosorbent assay. The percentual values of seroprevalence for *A. marginale* were submitted to χ^2 test, and the level of minimum significance, to keep a factor in the model of logistic regression, was fixated in 5%. It was observed that pregnancy and lactation influenced significantly ($p < 0.05$) in the seropositivity of the animals. *Bos indicus* animals had 5.21 times more chances of being seropositive than *B. taurus* animals. Primiparous female had 88% more chances of being seropositive than pluriparous female. Animals with high milk production were 63% more positive than low production animals. When infested by ticks the animals had 39% more chance of being seropositive to *A. marginale*. *Bos indicus* animals presented 5.21 times more chance of being seropositive than *B. taurus* animals. Primiparous females presented 88% more chance of being seropositive than the pluriparous ones. High milk production animals were 63% more positive than the low production ones. When infested by ticks the animals had 39% more chance of being seropositive to *A. marginale*. High density grazing provided for the animals 3.2 times more chances of being seropositive than low density ones. The herd was classified as erratic to *A. marginale*, even being placed in a steady enzootic area.

Key words: *Anaplasma marginale*, immunodiagnostic, postpartum, prevalence

Resumo

Anaplasma marginale é o mais prevalente patógeno de bovinos transmitido por carrapatos em todo o mundo. Este estudo objetivou avaliar os fatores de risco para anaplasmosse em vacas de leite. Foram selecionadas por amostragem estratificada proporcional 50 vacas do rebanho da Empresa de Pesquisa Agropecuária do Estado do Rio de Janeiro. Os fatores de risco avaliados foram: estado fisiológico, padrão racial, número de lactações, produção leiteira, infestação por *Rhipicephalus microplus* e densidade animal. A atividade de anticorpos contra *Anaplasma marginale* foi determinada utilizando o Ensaio de Imunoadsorção Enzimático Indireto. Os valores percentuais de soroprevalência para *A. marginale* foram submetidos ao teste χ^2 , sendo que o nível de significância mínima para manter um fator no modelo de regressão logística foi fixado em 5%. Observou-se que, tanto a gestação quanto a lactação influenciaram significativamente ($p < 0.05$) na soropositividade dos animais. Animais *Bos indicus* apresentaram 5,21

vezes mais chance de serem soropositivos do que animais *B. taurus*. Fêmeas primíparas apresentaram 88% mais chance de serem soropositivos do que fêmeas pluríparas. Animais com alta produção leiteira foram 63% mais positivos do que animais de baixa produção. Quando infestados por carrapatos os animais possuíam 39% mais chance de serem soropositivos para *A. marginale*. Pastejo sob alta densidade proporcionou aos animais 3,2 vezes mais chances de serem soropositivos do que baixa densidade. O rebanho foi classificado como instável para *A. marginale*, mesmo estando localizado em uma área de estabilidade enzoótica.

Introduction

Anaplasma marginale is the most prevalent bovine pathogen transmitted by ticks all around the world, existing in six continents and being responsible for high morbidity and mortality in warm, subtropical and tropical regions (PALMER, 1989). The disease is endemic in Latin America, where the main vector is *R. microplus* tick (GUGLIELMONE, 1995; VIDOTTO et al., 1998). The seroprevalence of *A. marginale* varies widely between the countries in Americas and the variability of these taxes contributes for the development of geographic steady regions.

In Brazil, the relation between the population of *R. microplus* ticks and bovine anaplasmosis creates two epidemiologic situations: the first one is observed in the regions where there is a seasonal fluctuation in the population of vectors that may be due to climatic conditions or because inadequate strategies in the control of ectoparasites (ARAÚJO et al., 2003). In these conditions, when the animals stay for a long time without contact with *A. marginale*, and then become infected, they can presented an accurate clinic disease with high taxes of mortality. In these cases the situation is called enzootic instability (RIBEIRO et al., 1984). The second situation occurs in endemic areas, where the vector population is present all over the year. In these regions the animals have more resistance to infection because they develop immunity in the first months of life while being infected by *A. marginale* when they are still protected by colostrum (ARAÚJO et al., 2003). This situation happens in enzootic steady areas where disease occurrences and high taxes of mortality are not usual.

The epidemiologic situation of the bovine anaplasmosis in the majority of Brazilian regions is of endemic stability (ARAÚJO et al., 1998). However, seroepidemiological studies have proved relevant variations in prevalence with instability areas, where ecologic and climatic factors do not help the development of *R. microplus* vector and of hematophagous dipterous spreader of *A. marginale* (SOUZA et al., 2000). In this context the aim of the study were the evaluation of risk factors to anaplasmosis and endemically characterize a property of dairy cattle in the municipality of Seropédica, Rio de Janeiro State-Brazil.

Materials e Methods

The field activities were conducted in 2008 and 2009, in the dairy cow section at the Seropédica Experimental Station, which belongs to the Agricultural and Livestock Research Company of the State of Rio de Janeiro (Empresa de Pesquisa Agropecuaria do Estado do Rio de Janeiro; Pesagro-Rio), located in the Rio de Janeiro Metropolitan microregion (latitude 22°45'S, longitude 43°41'W and altitude 33 meters).

To analyze risk factors, the animals were selected and categorized according to proportional stratified sampling, and 84 dairy cattle were randomly selected in this manner. Among these, 44 dairy cattle gave birth during the rainy seasons (spring and summer) and 40 during the dry seasons (fall and winter).

Among the dairy cattle evaluated, 20 were pure *Bos taurus* (Holstein), 28 were half-blood F1

through crossbreeding ($\frac{1}{2}$ *B. taurus* x $\frac{1}{2}$ *B. indicus*), 21 were Girolando ($\frac{3}{8}$ *B. indicus* x $\frac{3}{8}$ *B. taurus*) and 15 were pure *Bos indicus* (Gir). Regarding the number of lactations, 20 dairy cattle were at their first lactation, 25 at the second lactation, 24 at the third lactation and 15 at the fourth or subsequent lactation. In the milk production evaluation, the dairy cattle were classified according to their annual production. In the herd evaluated, 27 dairy cattle with milk production lower than 1500 kg were classified as low-production animals, 37 with milk production between 1500 and 3000 kg were classified as having moderate milk production, and 20 dairy cattle with production higher than 3000 kg were classified as high-production animals. To quantify the annual milk production, the study took into consideration 300 days of the year.

The animals were classified in four categories concerning to the level of infestation by *R. microplus*: absence of adult ticks, nymphs and larvae; slight infestation (among 1 and 10 tick engorging and few larvae and nymphs); average infestation (among 11 and 30 tick engorging and average quantity of larvae and nymphs), high infestation (above 31 tick engorging and many larvae and nymphs). In accordance with the routine management procedure at the experimental station, the pregnant dairy cattle were kept in an area of *Brachiaria decumbens* grass at an animal density of 5 AU/ha for the 30 days before calving. After calving and for the first four weeks of lactation, the animals were kept on *B. decumbens* and *Panicum maximum* pasture at an animal density of 3 AU/ha.

The sample collections of blood serum were done monthly in empty, dry and latent dairy cattle. There were two samplings in each group totalizing 600 samples, being 200 samples by group. However during peripartum the sampling was done weekly. During peripartum samplings were done 5 weeks before labor, in the week of labor and in the 5 weeks of postpartum, totalizing 550 samples.

Antibody activity against *A. marginale* was determined using the indirect enzyme-linked

immunosorbent assay (iELISA) according to Machado et al. (1997) for *Babesia bovis*, adapted for *A. marginale*. As positive controls bovine serum was used and kept with high quantity of antibodies anti-*A. marginale* and as negative controls serologically negative calf serum was used. Total antigen of *A. marginale* with concentration at 12 μ g/ml was used. The reading was done on ELISA reader in a wave length of 405nm.

The immunological activity of each serum was calculated by determining the sample to positive serum ratio (S/P) at each dilution, considering positive and negative sera as reference. S/P values were grouped into ELISA levels (EL), which ranged from 0 (lowest level) to 9 (highest level). The subsequent levels were determined by increment of 35% as described by Wilson et al. (1984) for the Newcastle system.

For the effect of area classification Mahoney and Ross (1972) criteria were used, that classified as enzootic stability the areas whose herd have antibodies frequency above 75%, areas of enzootic instability, those ones with frequencies inferior to 75% and marginal ones whose frequencies are close to the limit.

A qui-square or Fischer's exact tests were used to determine significant differences in percentages of positive results. Variables that were significantly associated with high/low herd seroprevalence at a with p -value ≤ 0.20 in a bivariable screening model were retained for further evaluation in multivariable models. The operational procedures were done using the R Foundation statistical computing software, version 2.12.2 (2011).

Results

It was observed absorption of 1.09 ± 0.132 to the positive controls ($n=15$) and 0.131 ± 0.017 to the negative controls ($n=15$). The titles of antibodies against *A. marginale* from dry, pregnant, during peripartum and lactating cow serums, kept in areas

infested by *Rhipicephalus microplus*, tested by iELISA are distributed in NE in Table 1.

The prevalence of *A. marginale* was of 30% and 35% in dry and pregnant dairy cattle respectively. During peripartum it was observed a significant reduction of serum prevalence (20%), being in the following period, lactation, the seropositivity raised substantially to 60%. These results demonstrate that

during the whole reproductive cycle the herd was epidemiologically instable to *A. marginale*.

The results related to univariate analysis to the evaluated extracts as risk factors associated to the frequency of against *A. marginale* antibodies are shown in Table 2.

Table 1. Classification of the test serum S/P (sample/Positive) in EL (ELISA Levels) varying from 0-9 in cattle naturally infected with *Anaplasma marginale*, Pesagro-Rio, 2008-2009.

The final model of multivariate logistic regression for the frequency of antibodies of IgG class against *A. marginale* in dairy cattle related to the physiologic state is represented in Table 3.

In the logistic model it was observed that lactating dairy cattle had 5.1 more chances of being serum positive to *A. marginale* than dry dairy cattle, *Bos indicus* animals had 5.21 more chances than

B. taurus animals. The reproductive experience directly influenced in the seropositivity to *A. marginale* because 1st lactation animals had 88% more chances of being positive than 2nd lactation ones. Low milk production animals had 63% more chances of having against *A. marginale* antibodies

than high production animals. In addition, low tick infestation animals had 39% more chances than moderate infestation animals. When kept in high density pasture it was observed that the animals has 3.2 more chances of being seropositive than animals kept in low density.

Discussion

The innate and acquired defense mechanisms in bovines are reduced during labor (MALLARD et al., 1998). This reduced answer capacity includes alterations in systemic, physical and metabolic immunity that substantially contributes to the decrease of resistance and the increase of infectious

and parasitic diseases in that period. In this study it was observed reduction of the quantity of antibodies during peripartum and lactation. These results clearly showed that in that period the animal were susceptible to anaplasmosis. So in studies of disease risks, in which antibodies are passively transferred by colostrum, peripartum dairy cattle must be considered as a risk group.

Some studies were done to determine the susceptibility of *B. indicus* and *B. taurus* bovines to infection by *A. marginale*. Parker, Shepherd and Trueman (1985) demonstrated that rickettsia is slightly superior to *B. taurus* in comparison to *B. indicus*, but the clinical signs are not different between the races. In addition it was concluded that serious reactions happened in both races implying that in a field situation zebuine do not present more resistance to anaplasmosis in comparison to the taurine ones. However it was noticed that the quantity of *B. taurus* and *B. indicus* antibodies significantly varied in all studied groups, demonstrating that taurine animals can be more vulnerable to *A. marginale* due to the lower quantity of circulating antibodies.

Bock, Kingston and De Vos (1999) studied the susceptibility of taurine and zebuine bovines in pasture infested by *R. microplus* infected with an isolated virulent of *A. marginale*. The authors observed that although there was no significant difference between races in resisting to the infection there was a considerable variation in the resistance to *A. marginale* in both races and the mortality was higher in *B. taurus* animals. The authors concluded that *A. marginale* could infect both races in their crossbreeding, however it causes considerable losses in *B. taurus* races.

Concerning to the reproductive experience the observed results in this study are similar to the ones seen by Larson and Hays (1958) and Dixon, Hart and Fouts (1961). According to these authors an important source of variation of the levels of immunoglobulin in colostrum is related to the reproductive experience, considering that primiparous dairy cattle usually produce an inferior quality of colostrum. So first lactation dairy cattle, due to the lower quantity of antibodies passed through colostrum, ending up circulating a higher quantity of immunoglobulin. The low quantity of antibodies in older animals may be credited to the debility of the immune system due to age.

Besser and Gay (1994) observed that high production animals are characterized in general for showing more elevated global levels of IgG in their colostrum than low production animals. In milk dairy cattle due to specialization it was showed that migration of serum immunoglobulin to the mammal glands, during the formation of colostrum, determines a decrease in concentration of this protein in the blood stream, in the last weeks of peripartum (DIXON; HART; FOUTS, 1961). In this study high production dairy cattle had less quantity of circulating antibodies in all physiological phases. These results indicate that, beyond the passive passing of higher quantity of immunoglobulin to colostrum, the genetic for high production may also be associated to the low quantity of antibodies against *A. marginale*.

The increase of *R. Microplus* density was associated to the decrease in risk for the occurrence of anaplasmosis. This tendency of serum conversion risk is probably associated to the increase of the transmission of the agent to the animals from the herd. In the herd by studying the practices of parasite control it results in a low population of the vector maybe insufficient to keep constantly the transmission of *A. marginale*. According to Mahoney and Ross (1972), in this case an unbalance caused by the parasite-host relation due to the infrequent transmission it creates an artificial condition of endemic instability, where seasonally happens clinic cases in the period of maximum activity of the vectors.

According to Swai et al. (2005) in univariate analysis, the number of adult *R. appendiculatus* had significant association with a higher probability of an animal presenting serum conversion to *A. marginale* (coefficient = 0.039 e $P < 0.01$). When this same analysis was done to *R. microplus* it was not observed significant association to this agent. In our study, even after the analysis of logistic regression, the infestation by *R. microplus* is an important risk factor to anaplasmosis.

This study corroborates to Rodríguez-Vivas et al. (2004) who observed higher seroprevalence to *A. marginale* in animals kept in density superior to 1 animal/ha (OR=10.94). Pérez et al. (1994), considerate that high animal density was the factor the contributed the most for the high seroprevalence of *A. marginale* in studies done in California, South part of New Zealand and Costa Rica. Guglielmone (1995) also observed that *A. marginale* vectors, including *R. microplus* have a high probability of been fed in susceptible animals and consequently do inoculation of large quantity of inoculum when there is high animal density.

Conclusion

Not only environmental factors as intrinsic factor are important to the epidemiology of anaplasmosis but also these factors must be analyzed together with other factors such as: kinds of pasture, animal density, vector density and control measure to classify the properties concerning to the risk of occurrence of disease in endemic areas to *A. marginale*.
